Part 11: Pediatric Basic Life Support

For best survival and quality of life, pediatric basic life support (BLS) should be part of a community effort that includes prevention, basic CPR, prompt access to the emergency medical services (EMS) system, and prompt pediatric advanced life support (PALS). These 4 links form the American Heart Association (AHA) pediatric Chain of Survival (Figure 1). The first 3 links constitute pediatric BLS.

Rapid and effective bystander CPR is associated with successful return of spontaneous circulation and neurologically intact survival in children.1,2 The greatest impact occurs in respiratory arrest,3 in which neurologically intact survival rates of >70% are possible,4-6 and in ventricular fibrillation (VF), in which survival rates of 30% have been documented.7 But only 2% to 10% of all children who develop out-of-hospital cardiac arrest survive, and most are neurologically devastated.7,8-11 Part of the disparity is that bystander CPR is provided for less than half of the victims of out-of-hospital arrest.8,11,14 Some studies show that survival and neurologic outcome can be improved with prompt CPR.6,15-17

Prevention of Cardiopulmonary Arrest
The major causes of death in infants and children are respiratory failure, sudden infant death syndrome (SIDS), sepsis, neurologic diseases, and injuries.18

Injuries
Injuries, the leading cause of death in children and young adults, cause more childhood deaths than all other causes combined.18 Many injuries are preventable. The most common fatal childhood injuries amenable to prevention are motor vehicle passenger injuries, pedestrian injuries, bicycle injuries, drowning, burns, and firearm injuries.19

Motor Vehicle Injuries
Motor vehicle–related injuries account for nearly half of all pediatric deaths in the United States.18 Contributing factors include failure to use proper passenger restraints, inexperienced adolescent drivers, and alcohol.

Appropriate restraints include properly installed, rear-facing infant seats for infants <20 pounds (<9 kg) and <1 year of age, child restraints for children 1 to 4 years of age, and booster seats with seat belts for children 4 to 7 years of age.20 The lifesaving benefit of air bags for older children and adults far outweighs their risk. Most pediatric air bag–related fatalities occur when children <12 years of age are in the vehicle’s front seat or are improperly restrained for their age. For additional information consult the website of the National Highway Traffic Safety Administration (NHTSA): http://nhtsa.gov. Look for the Comprehensive Child Passenger Safety Information.

Adolescent drivers are responsible for a disproportionate number of motor vehicle–related injuries; the risk is highest in the first 2 years of driving. Driving with teen passengers and driving at night dramatically increase the risk. Additional risks include not wearing a seat belt, drinking and driving, speeding, and aggressive driving.21

Pedestrian Injuries
Pedestrian injuries account for a third of motor vehicle–related injuries. Adequate supervision of children in the street is important because injuries typically occur when a child darts out mid-block, dashes across intersections, or gets off a bus.22

Bicycle Injuries
Bicycle crashes are responsible for approximately 200 000 injuries and nearly 150 deaths per year in children and adolescents.23 Head injuries are a major cause of bicycle-related morbidity and mortality. It is estimated that bicycle helmets can reduce the severity of head injuries by >80%.24

Burns
Approximately 80% of fire-related and burn-related deaths result from house fires and smoke inhalation.25,26 Smoke detectors are the most effective way to prevent deaths and injuries; 70% of deaths occur in homes without functioning smoke alarms.27

Firearm Injuries
The United States has the highest firearm-related injury rate of any industrialized nation—more than twice that of any other country.28 The highest number of deaths is in adolescents and young adults, but firearm injuries are more likely to be fatal in young children.29 The presence of a gun in the home is associated with an increased likelihood of adolescent30,31 and adult suicides or homicides.32 Although overall firearm-related deaths declined from 1995 to 2002, firearm homicide remains the leading cause of death among African-American adolescents and young adults.18

Sudden Infant Death Syndrome
SIDS is “the sudden death of an infant under 1 year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.”33 The peak incidence of SIDs occurs in infants 2 to 4 months of
age. The etiology of SIDS remains unknown, but risk factors include prone sleeping position, sleeping on a soft surface, and second-hand smoke. The incidence of SIDS has declined 40% since the “Back to Sleep” public education campaign was introduced in the United States in 1992. This campaign aims to educate parents about placing an infant on the back rather than the abdomen or side to sleep.

Drowning
Drowning is the second major cause of death from unintentional injury in children <5 years of age and the third major cause of death in adolescents. Most young children drown after falling into swimming pools while unsupervised; adolescents more commonly drown in lakes and rivers while swimming or boating. Drowning can be prevented by installing isolation fencing around swimming pools (gates should be self-closing and self-latching) and wearing personal flotation devices (life jackets) while in, around, or on water.

The BLS Sequence for Infants and Children
For the purposes of these guidelines, an “infant” is less than approximately 1 year of age. This section does not deal with newborn infants (see Part 13: “Neonatal Resuscitation Guidelines”). For lay rescuers the “child” BLS guidelines should be applied when performing CPR for a child from about 1 year of age to about 8 years of age. For a healthcare provider, the pediatric (“child”) guidelines apply from about 1 year to about the start of puberty. For an explanation of the differences in etiology of arrest and elaboration of the differences in the recommended sequence for lay rescuer and healthcare provider CPR for infants, children, and adults, see Part 3: “Overview of CPR.”

These guidelines delineate a series of skills as a sequence of distinct steps, but they are often performed simultaneously (eg, starting CPR and activating the EMS system), especially when more than one rescuer is present. This sequence is depicted in the Pediatric Healthcare Provider BLS Algorithm (Figure 2). The numbers listed with the headings below refer to the corresponding box in that algorithm.

Safety of Rescuer and Victim
Always make sure that the area is safe for you and the victim. Move a victim only to ensure the victim’s safety. Although exposure to a victim while providing CPR carries a theoretical risk of infectious disease transmission, the risk is very low.

Check for Response (Box 1)
- Gently tap the victim and ask loudly, “Are you okay?” Call the child’s name if you know it.
- Look for movement. If the child is responsive, he or she will answer or move. Quickly check to see if the child has any injuries or needs medical assistance. If necessary, leave the child to phone EMS, but return quickly and recheck the child’s condition frequently. Children with respiratory distress often assume a position that maintains airway patency and optimizes ventilation. Allow the child with respiratory distress to remain in a position that is most comfortable.
- If the child is unresponsive and is not moving, shout for help and start CPR. If you are alone, continue CPR for 5 cycles (about 2 minutes). One cycle of CPR for the lone rescuer is 30 compressions and 2 breaths (see below). Then activate the EMS system and get an automated external defibrillator (AED) (see below). If you are alone and there is no evidence of trauma, you may carry a small child with you to the telephone. The EMS dispatcher can guide you through the steps of CPR. If a second rescuer is present, that rescuer should immediately activate the EMS system and get an AED (if the child is 1 year of age or older) while you continue CPR. If you suspect trauma, the second rescuer may assist by stabilizing the child’s cervical spine (see below). If the child must be moved for safety reasons, support the head and body to minimize turning, bending, or twisting of the head and neck.

Activate the EMS System and Get the AED (Box 2)
If the arrest is witnessed and sudden (eg, an athlete who collapses on the playing field), a lone healthcare provider should activate the EMS system (by telephoning 911 in most locales) and get an AED (if the child is 1 year of age or older) before starting CPR. It would be ideal for the lone lay rescuer who witnesses the sudden collapse of a child to also activate the EMS system and get an AED and return to the child to begin CPR and use the AED. But for simplicity of lay rescuer education it is acceptable for the lone lay rescuer to provide about 5 cycles (about 2 minutes) of CPR for any infant or child victim before leaving to phone 911 and get an AED (if appropriate). This sequence may be tailored for some learners (eg, the mother of a child at high risk for a sudden arrhythmia). If two rescuers are present, one rescuer should begin CPR while the other rescuer activates the EMS system and gets the AED.

Position the Victim
If the victim is unresponsive, make sure that the victim is in a supine (face up) position on a flat, hard surface, such as a sturdy table, the floor, or the ground. If you must turn the victim, minimize turning or twisting of the head and neck.

Open the Airway and Check Breathing (Box 3)
In an unresponsive infant or child, the tongue may obstruct the airway, so the rescuer should open the airway.

Open the Airway: Lay Rescuer
If you are a lay rescuer, open the airway using a head tilt–chin lift maneuver for both injured and noninjured victims (Class IIa). The jaw thrust is no longer recommended for lay rescuers because it is difficult to learn and perform, is often not an effective way to open the airway, and may cause spinal movement (Class IIb).

Open the Airway: Healthcare Provider
A healthcare provider should use the head tilt–chin lift maneuver to open the airway of a victim without evidence of head or neck trauma.

Downloaded from circ.ahajournals.org by on April 10, 2010
Approximately 2% of all victims with blunt trauma requiring spinal imaging in an emergency department have a spinal injury. This risk is tripled if the victim has craniofacial injury, a Glasgow Coma Scale score of \(<8\), or both. If you are a healthcare provider and suspect that the victim may have a cervical spine injury, open the airway using a jaw thrust without head tilt (Class IIb). Because maintaining a patent airway and providing adequate ventilation is a priority in CPR (Class I), use a head tilt–chin lift maneuver if the jaw thrust does not open the airway.

**Check Breathing (Box 3)**

While maintaining an open airway, take no more than 10 seconds to check whether the victim is breathing: Look for rhythmic chest and abdominal movement, listen for exhaled breath sounds at the nose and mouth, and feel for exhaled air on your cheek. Periodic gasping, also called agonal gasps, is not breathing.

1. If the child is **breathing** and there is no evidence of trauma: turn the child onto the side (recovery position, Figure 3). This helps maintain a patent airway and decreases risk of aspiration.

2. **Give Rescue Breaths (Box 4)**

If the child is **not breathing** or has only occasional gasps:

- For the lay rescuer: maintain an open airway and give 2 breaths.
- For the healthcare provider: maintain an open airway and give 2 breaths. Make sure that the breaths are effective (ie, the chest rises). If the chest does not rise, reposition the head, make a better seal, and try again. It may be necessary to move the child’s head through a range of positions to obtain optimal airway patency and effective rescue breathing.
In an infant, use a mouth-to–mouth-and-nose technique (LOE 7; Class IIb); in a child, use a mouth-to-mouth technique.55

Comments on Technique
In an infant, if you have difficulty making an effective seal over the mouth and nose, try either mouth-to-mouth or mouth-to-nose ventilation (LOE 5; Class IIb).56–58 If you use the mouth-to-mouth technique, pinch the nose closed. If you use the mouth-to-nose technique, close the mouth. In either case make sure the chest rises when you give a breath.

Barrier Devices
Despite its safety,42 some healthcare providers59–61 and lay rescuers8,62,63 may hesitate to give mouth-to-mouth rescue breathing and prefer to use a barrier device. Barrier devices have not reduced the risk of transmission of infection,42 and some may increase resistance to air flow.64,65 If you use a barrier device, do not delay rescue breathing.

Bag-Mask Ventilation (Healthcare Providers)
Bag-mask ventilation can be as effective as endotracheal intubation and safer when providing ventilation for short periods.66–69 But bag-mask ventilation requires training and periodic retraining in the following skills: selecting the correct mask size, opening the airway, making a tight seal between the mask and face, delivering effective ventilation, and assessing the effectiveness of that ventilation. In the out-of-hospital setting, preferentially ventilate and oxygenate infants and children with a bag and mask rather than attempt intubation if transport time is short (Class IIa; LOE 166, 367, 468,69).

Ventilation Bags
Use a self-inflating bag with a volume of at least 450 to 500 mL70; smaller bags may not deliver an effective tidal volume or the longer inspiratory times required by full-term neonates and infants.71

A self-inflating bag delivers only room air unless supplemental oxygen is attached, but even with an oxygen inflow of 10 L/min, the concentration of delivered oxygen varies from 30% to 80% and depends on the tidal volume and peak inspiratory flow rate.72 To deliver a high oxygen concentration (60% to 95%), attach an oxygen reservoir to the self-inflating bag. You must maintain an oxygen flow of 10 to 15 L/min into a reservoir attached to a pediatric bag72 and a flow of at least 15 L/min into an adult bag.

Precautions
Avoid hyperventilation; use only the force and tidal volume necessary to make the chest rise. Give each breath over 1 second.

● In a victim of cardiac arrest with no advanced airway in place, pause after 30 compressions (1 rescuer) or 15 compressions (2 rescuers) to give 2 ventilations when using either mouth-to-mouth or bag-mask technique.

● During CPR for a victim with an advanced airway (eg, endotracheal tube, esophageal-tracheal combitube [Combi-tube], or laryngeal mask airway [LMA]) in place, rescuers should no longer deliver “cycles” of CPR. The compressing rescuer should compress the chest at a rate of 100 times per minute without pauses for ventilations, and the rescuer providing the ventilation should deliver 8 to 10 breaths per minute. Two or more rescuers should change the compressor role approximately every 2 minutes to prevent compressor fatigue and deterioration in quality and rate of chest compressions.

● If the victim has a perfusing rhythm (ie, pulses are present) but no breathing, give 12 to 20 breaths per minute (1 breath every 3 to 5 seconds).

Healthcare providers often deliver excessive ventilation during CPR,73–75 particularly when an advanced airway is in place. Excessive ventilation is detrimental because it

● Impedes venous return and therefore decreases cardiac output, cerebral blood flow, and coronary perfusion by increasing intrathoracic pressure74

● Causes air trapping and barotrauma in patients with small-airway obstruction

● Increases the risk of regurgitation and aspiration

Rescuers should provide the recommended number of rescue breaths per minute.

You may need high pressures to ventilate patients with airway obstruction or poor lung compliance. A pressure-relief valve can prevent delivery of sufficient tidal volume.72 Make sure that the manual bag allows you to use high pressures if necessary to achieve visible chest expansion.76

Two-Person Bag-Mask Ventilation
A 2-person technique may be necessary to provide effective bag-mask ventilation when there is significant airway obstruction, poor lung compliance,76 or difficulty in creating a tight seal between the mask and the face. One rescuer uses both hands to open the airway and maintain a tight mask-to-face seal while the other compresses the ventilation bag. Both rescuers should observe the chest to ensure chest rise.

Gastric Inflation and Cricoid Pressure
Gastric inflation may interfere with effective ventilation77 and cause regurgitation. To minimize gastric inflation:

● Avoid excessive peak inspiratory pressures (eg, ventilate slowly).66
• Apply cricoid pressure. Do this only in an unresponsive victim and if there is a second rescuer. Avoid excessive pressure so as not to obstruct the trachea.

**Oxygen**

Despite animal and theoretic data suggesting possible adverse effects of 100% oxygen, there are no studies comparing various concentrations of oxygen during resuscitation beyond the newborn period. Until additional information becomes available, healthcare providers should use 100% oxygen during resuscitation (Class Indeterminate). Once the patient is stable, wean supplementary oxygen but ensure adequate oxygen delivery by appropriate monitoring. Whenever possible, humidify oxygen to prevent mucosal drying and thickening of pulmonary secretions.

**Masks**

Masks provide an oxygen concentration of 30% to 50% to a victim with spontaneous breathing. For a higher concentration of oxygen, use a tight-fitting nonrebreathing mask with an oxygen inflow rate of approximately 15 L/min that maintains inflation of the reservoir bag.

**Nasal Cannulas**

Infant and pediatric size nasal cannulas are suitable for children with spontaneous breathing. The concentration of delivered oxygen depends on the child’s size, respiratory rate, and respiratory effort. For example, a flow rate of only 2 L/min can provide young infants with an inspired oxygen concentration >50%.

**Pulse Check (for Healthcare Providers) (Box 5)**

If you are a healthcare provider, you should palpate a pulse (brachial in an infant and carotid or femoral in a child). Take no more than 10 seconds. Studies show that healthcare providers as well as lay rescuers are unable to reliably detect a pulse and at times will think a pulse is present when there is no pulse. For this reason, if you do not definitely feel a pulse (eg, there is no pulse or you are not sure you feel a pulse) within 10 seconds, proceed with chest compressions.

If despite oxygenation and ventilation the pulse is <60 beats per minute (bpm) and there are signs of poor perfusion (ie, pallor, cyanosis), begin chest compressions. Profound bradycardia in the presence of poor perfusion is an indication for chest compressions because an inadequate heart rate with poor perfusion indicates that cardiac arrest is imminent. Cardiac output in infancy and childhood largely depends on heart rate. No scientific data has identified an absolute heart rate at which chest compressions should be initiated; the recommendation to provide cardiac compression for a heart rate <60 bpm with signs of poor perfusion is based on ease of teaching and skills retention. For additional information see “Bradycardia” in Part 12: “Pediatric Advanced Life Support.”

If the pulse is ≥60 bpm but the infant or child is not breathing, provide rescue breathing without chest compressions (see below).

Lay rescuers are not taught to check for a pulse. The lay rescuer should immediately begin chest compressions after delivering 2 rescue breaths.

**Rescue Breathing Without Chest Compressions (for Healthcare Providers Only) (Box 5A)**

If the pulse is ≥60 bpm but there is no spontaneous breathing or inadequate breathing, give rescue breaths at a rate of about 12 to 20 breaths per minute (1 breath every 3 to 5 seconds) until spontaneous breathing resumes (Box 5A). Give each breath over 1 second. Each breath should cause visible chest rise.

During delivery of rescue breaths, reassess the pulse about every 2 minutes (Class IIa), but spend no more than 10 seconds doing so.

**Chest Compressions (Box 6)**

To give chest compressions, compress the lower half of the sternum but do not compress over the xiphoid. After each compression allow the chest to recoil fully (Class IIb). Because complete chest reexpansion improves blood flow into the heart, a manikin study showed that one way to ensure complete recoil is to lift your hand slightly off the chest at the end of each compression, but this has not been studied in humans (Class Indeterminate). The following are characteristics of good compressions:

• “Push hard”: push with sufficient force to depress the chest approximately one third to one half the anterior-posterior diameter of the chest.
• “Push fast”: push at a rate of approximately 100 compressions per minute.
• Release completely to allow the chest to fully recoil.
• Minimize interruptions in chest compressions.

In an infant victim, lay rescuers and lone rescuers should compress the sternum with 2 fingers (Figure 4) placed just below the intermammary line (Class IIb; LOE 5, 6).

The 2 thumb–encircling hands technique (Figure 5) is recommended for healthcare providers when 2 rescuers are present. Encircle the infant’s chest with both hands; spread your fingers around the thorax, and place your thumbs together over the lower half of the sternum. Forcefully compress the sternum with your thumbs as you squeeze the thorax with your fingers for counterpressure (Class IIa; LOE...
with 2 hands. Because children and rescuers come in all
compression pressures can be obtained on a child manikin
that shows a 1-hand or 2-hand method to be superior; higher
not press on the xiphoid or the ribs. There is no outcome data
hand or with 2 hands (as used for adult victims) but should
compress the lower half of the sternum with the heel of 1

Ventilations are relatively less important during the first
●

The ideal compression-ventilation ratio is unknown, but
studies have emphasized the following:

- In 2000 a compression-ventilation ratio of 5:1 and a
  compression rate of 100 per minute were recommended.
  But at that ratio and compression rate, fewer than 50
  compressions per minute were performed in an adult
  manikin, and fewer than 60 compressions per minute
  were performed in a pediatric manikin even under ideal
  circumstances.

- It takes a number of chest compressions to raise coronary
  perfusion pressure, which drops with each pause (eg, to
  provide rescue breathing, check for a pulse, attach an
  AED).

- Long and frequent interruptions in chest compressions
  have been documented during CPR by lay rescuers and
  by healthcare providers in the out-of-hospital and in-hospital
  settings. Interruptions in chest compressions are associated
  with decreased rate of return of spontaneous circulation.

- Ventilations are relatively less important during the first
  minutes of CPR for victims of a sudden arrhythmia-
  induced cardiac arrest (VF or pulseless ventricular
tachycardia [VT]) than they are after asphyxia-induced
arrest, but even in asphyxial arrest, a minute
ventilation that is lower than normal is likely to maintain an
adequate ventilation-perfusion ratio because cardiac output
and, therefore, pulmonary blood flow produced by chest
compressions is quite low.

- For lay rescuers, a single compression-ventilation ratio
  (30:2) for all age groups may increase the number of
  bystanders who perform CPR because it is easier to
  remember.

If you are the only rescuer, perform cycles of 30 chest
compressions (Class Indeterminate) followed by 2 effective
ventilations with as short a pause in chest compressions as
possible (Class IIb). Make sure to open the airway before
giving ventilations.

For 2-rescuer CPR (eg, by healthcare providers or others,
such as lifeguards, who are trained in this technique), one
provider should perform chest compressions while the other
maintains the airway and performs ventilations at a ratio of
15:2 with as short a pause in compressions as possible. Do not
ventilate and compress the chest simultaneously with either
mouth-to-mouth or bag-mask ventilation. The 15:2 ratio for 2
rescuers is applicable in children up to the start of puberty.

Rescuer fatigue can lead to inadequate compression rate
and depth and may cause the rescuer to fail to allow complete
chest wall recoil between compressions. The quality of
chest compressions deteriorates within minutes even when
the rescuer denies feeling fatigued. Once an advanced
airway is in place for infant, child, or adult victims, 2 rescuers
no longer deliver cycles of compressions interrupted with
pauses for ventilation. Instead, the compressing rescuer
should deliver 100 compressions per minute continuously
without pauses for ventilation. The rescuer delivering the
ventilations should give 8 to 10 breaths per minute and should
be careful to avoid delivering an excessive number of
ventilations. Two or more rescuers should rotate the com-
pressor role approximately every 2 minutes to prevent com-
pressor fatigue and deterioration in quality and rate of chest
compressions. The switch should be accomplished as quickly
as possible (ideally in less than 5 seconds) to minimize
interruptions in chest compressions.

Compression-Only CPR
Ventilation may not be essential in the first minutes of VF
cardiac arrest, during which periodic gasps and
passive chest recoil may provide some ventilation if the
airway is open. This, however, is not true for most cardiac
arrests in infants and children, which are more likely to be
asphyxial cardiac arrest. These victims require both prompt
ventilations and chest compressions for optimal resuscitation.
If a rescuer is unwilling or unable to provide ventilations,
chest compressions alone are better than no resuscitation at
all (LOE 5 through 7; Class IIb).

Activate the EMS System and Get the AED (Box 7)
In the majority of infants and children with cardiac arrest, the
arrest is asphyxial. Lone rescuers (with the exception
of healthcare providers who witness sudden collapse)
should perform CPR for 5 cycles (about 2 minutes) before

Figure 5. Two thumb-encircling hands chest compression in
infant (2 rescuers).
activating EMS, then start CPR again with as few interruptions of chest compressions as possible. If there are more rescuers present, one rescuer should begin the steps of CPR as soon as the infant or child is found to be unresponsive and a second rescuer should activate the EMS system and get an AED. Minimize interruption of chest compressions.

Defibrillation (Box 8)

VF can be the cause of sudden collapse, or it may develop during resuscitation attempts.\footnote{134,135} Children with sudden witnessed collapse (eg, a child collapsing during an athletic event) are likely to have VF or pulseless VT and need immediate CPR and rapid defibrillation. VF and pulseless VT are referred to as “shockable rhythms” because they respond to electric shocks (defibrillation).

Many AEDs have high specificity in recognizing pediatric shockable rhythms, and some are equipped to decrease the delivered energy to make it suitable for children 1 to 8 years of age.\footnote{136–138} Since the publication of the ECC Guidelines 2000,\footnote{112} data has shown that AEDs can be safely and effectively used in children 1 to 8 years of age.\footnote{136–138} However, there is insufficient data to make a recommendation for or against using an AED in infants <1 year of age (Class Indeterminate).\footnote{136–138}

In systems and institutions that care for children and have an AED program, it is recommended that the AED have both a high specificity in recognizing pediatric shockable rhythms and a pediatric dose-attenuating system to reduce the dose delivered by the device. In an emergency if an AED with a pediatric attenuating system is not available, use a standard AED. Turn the AED on, follow the AED prompts, and resume chest compressions immediately after the shock. Minimize interruptions in chest compressions.

CPR Techniques and Adjuncts

There is insufficient data in infants and children to recommend for or against the use of mechanical devices to compress the sternum, active compression-decompression CPR, interposed abdominal compression CPR (IAC-CPR), or the impedance threshold device (Class Indeterminate). See Part 6: “CPR Techniques and Devices” for adjuncts in adults.

Foreign-Body Airway Obstruction (Choking)

Epidemiology and Recognition

More than 90% of deaths from foreign-body aspiration occur in children <5 years of age; 65% of the victims are infants. Liquids are the most common cause of choking in infants,\footnote{139} whereas balloons, small objects, and foods (eg, hot dogs, round candies, nuts, and grapes) are the most common causes of foreign-body airway obstruction (FBAO) in children.\footnote{140–144} Signs of FBAO include a sudden onset of respiratory distress with coughing, gagging, stridor (a high-pitched, noisy sound), or wheezing. The characteristics that distinguish FBAO from other causes (eg, croup) are sudden onset in a proper setting and the absence of antecedent fever or respiratory symptoms.

Relief of FBAO

FBAO may cause mild or severe airway obstruction. When the airway obstruction is mild, the child can cough and make some sounds. When the airway obstruction is severe, the victim cannot cough or make any sound.

- If FBAO is mild, do not interfere. Allow the victim to clear the airway by coughing while you observe for signs of severe FBAO.
- If the FBAO is severe (ie, the victim is unable to make a sound):
  - For a child, perform subdiaphragmatic abdominal thrusts (Heimlich maneuver)\footnote{145,144} until the object is expelled or the victim becomes unresponsive. For an infant, deliver 5 back blows (slaps) followed by 5 chest thrusts\footnote{145–149} repeatedly until the object is expelled or the victim becomes unresponsive. Abdominal thrusts are not recommended for infants because they may damage the relatively large and unprotected liver.\footnote{150–152}
  - If the victim becomes unresponsive, lay rescuers and healthcare providers should perform CPR but should look into the mouth before giving breaths. If you see a foreign body, remove it. Healthcare providers should not perform blind finger sweeps because they may push obstructing objects further into the pharynx and may damage the oropharynx.\footnote{153,154} Healthcare providers should attempt to remove an object only if they can see it in the pharynx. Then rescuers should attempt ventilation and follow with chest compressions.

Special Resuscitation Situations

Children With Special Healthcare Needs

Children with special healthcare needs\footnote{155–157} may require emergency care for complications of chronic conditions (eg, obstruction of a tracheostomy), failure of support technology (eg, ventilator failure), progression of underlying disease, or events unrelated to those special needs. Care is often complicated by a lack of medical information, plan of medical care, list of current medications, and Do Not Attempt Resuscitation (DNAR) orders. Parents and child-care providers are encouraged to keep copies of medical information at home, with the child, and at the child’s school or child-care facility. School nurses should have copies and should maintain a readily available list of children with DNAR orders.\footnote{158,159} An Emergency Information Form (EIF) was developed by the American Academy of Pediatrics and the American College of Emergency Physicians\footnote{157} and is available on the Worldwide Web at http://www.pediatrics.org/cgi/content/full/104/4/e53.

If a decision to limit or withhold resuscitative efforts is made, the physician must write an order clearly detailing the limits of any attempted resuscitation. A separate order must be written for the out-of-hospital setting. Regulations regarding out-of-hospital “do not attempt resuscitation” (DNAR or so-called “no-CPR”) directives vary from state to state. For further information about ethical issues of resuscitation, see Part 2: “Ethical Issues.”

When a child with a chronic or potentially life-threatening condition is discharged from the hospital, parents, school nurses, and home healthcare providers should be informed about the reason for hospitalization, hospital course, and how
to recognize signs of deterioration. They should receive specific instructions about CPR and whom to contact.\textsuperscript{159}

**Ventilation With a Tracheostomy or Stoma**

Everyone involved with the care of a child with a tracheostomy (parents, school nurses, and home healthcare providers) should know how to assess patency of the airway, clear the airway, and perform CPR using the artificial airway.

Use the tracheostomy tube for ventilation and verify adequacy of airway and ventilation by watching for chest expansion. If the tracheostomy tube does not allow effective ventilation even after suctioning, replace it. Alternative ventilation methods include mouth-to-stoma ventilation and bag-mask ventilation through the nose and mouth while you or someone else occludes the tracheal stoma.

**Trauma**

The principles of BLS resuscitation for the injured child are the same as those for the ill child, but some aspects require emphasis; improper resuscitation is a major cause of preventable pediatric trauma death.\textsuperscript{160} Errors include failure to properly open and maintain the airway and failure to recognize and treat internal bleeding.

The following are important aspects of resuscitation of pediatric victims of trauma:

- Anticipate airway obstruction by dental fragments, blood, or other debris. Use a suction device if necessary.
- Stop all external bleeding with pressure.
- When the mechanism of injury is compatible with spinal injury, minimize motion of the cervical spine and avoid traction or movement of the head and neck. Open and maintain the airway with a jaw thrust and try not to tilt the head. If a jaw thrust does not open the airway, use a head tilt–chin lift. If there are 2 rescuers, the first opens the airway while the second restricts cervical spine motion. To limit spine motion, secure at least the thighs, pelvis, and shoulders to the immobilization board. Because of the disproportionately large size of the head in infants and young children, optimal positioning may require repositioning the occiput\textsuperscript{161} or elevating the torso to avoid undesirable backboard-induced cervical flexion.\textsuperscript{161,162}
- If possible, transport children with multisystem trauma to a trauma center with pediatric expertise.

**Drowning**

Outcome after drowning depends on the duration of submersion, the water temperature, and how promptly CPR is started.\textsuperscript{1,16,163} An excellent outcome can occur after prolonged submersion in icy waters.\textsuperscript{164,165} Start resuscitation by safely removing the victim from the water as rapidly as possible. If you have special training, start rescue breathing while the victim is still in the water\textsuperscript{166} if doing so will not delay removing the victim from the water. Do not attempt chest compressions in the water, however.

There is no evidence that water acts as an obstructive foreign body; don’t waste time trying to remove water from the victim. Start CPR by opening the airway and giving 2 effective breaths followed by chest compressions; if you are alone, continue with 5 cycles (about 2 minutes) of compressions and ventilations before activating EMS and (for children 1 year of age and older) getting an AED. If 2 rescuers are present, send the second rescuer to activate the EMS system immediately and get an AED (if appropriate), while you continue CPR.

**Summary: The Quality of BLS**

Immediate CPR can improve survival from cardiorespiratory arrest in children, but not enough children receive high-quality CPR. We must increase the number of laypersons who learn, remember, and perform CPR and must improve the quality of CPR provided by lay rescuers and healthcare providers alike.

Systems that deliver professional CPR should implement processes of continuous quality improvement that include monitoring the quality of CPR delivered at the scene of cardiac arrest, other process-of-care measures (eg, initial rhythm, bystander CPR, and response intervals), and patient outcome up to hospital discharge (see Part 3: “Overview of CPR”). This evidence should be used to optimize the quality of CPR delivered (Class Indeterminate).
